To characterize the sonographic appearance of focal nodular hyperplasia (FNH) of the liver by correlating it with histopathologic findings. The institutional review board approved this retrospective study, and the need for patient informed consent was waived. Two radiologists retrospectively reviewed the sonographic findings in 1,780 FNH cases with tumor-to-liver attenuation ratios less than 15%, and the largest tumor diameter was less than or equal to 10 cm. The sonographic features of FNH were categorized into three types: diffuse, multinodular (mixed), and focal (single). The density of the dominant nodule was correlated with the histopathologic features. The mean +/- standard deviation (SD) of the tumor-to-liver attenuation ratio was 9.7% +/- 3.8%. Of the 1,780 cases, 1,616 (89.2%) were diffuse (1,468 [76.9%] were focal, and 348 [19.2%] were multinodular), and 264 (14.6%) were focal (249 [13.5%] were multinodular). FNH was mixed in 41 (2.3%). Of the 1,780 cases, 1,596 (91.1%) were solid, and 184 (10.5%) were cystic or contained echogenic septa. The most frequent echogenicity was either hypoechoic (1,366 [73.6%]) or isoechoic (351 [19.6%]). More than 80% of FNH showed a minimal or no change in echogenicity during the follow-up period of 3.0 years (range, 0.0-23.5 years). FNH shows a unique sonographic appearance that allows more accurate identification than conventional hepatic lesion imaging with dynamic computed tomography or magnetic resonance imaging. we're ready to move, we're ready to start, we're ready to finish," he said. "I think it's just a question of pushing ourselves to do it." The good news for the Spurs
